Abstract. Dissolved organic nitrogen (DON) is an abundant but poorly understood pool of N in many ecosystems. We assessed DON cycling in a N-limited headwater forest stream via whole-ecosystem additions of dissolved inorganic nitrogen (DIN) and labile dissolved organic matter (DOM), hydrologic transport and biogeochemical modeling, and laboratory experiments with native sediments. We sampled surface and subsurface waters to understand how interaction among hydrologic exchange, DIN, DON, and dissolved organic carbon (DOC) influence stream N losses at summer baseflow. Added DON was taken up rapidly from the water column at rates exceeding DOC and DIN. A significant fraction of this DON was mineralized and nitrified. Combined DON and NO_3-N uptake lengths resulted in spiraling lengths of ~210 m, suggesting the potential for multiple transformations of labile N loads within catchment boundaries. Simultaneous addition of DIN increased DOM uptake, but more so for C, resulting in an upward shift in the C:N ratio of uptake. Sediment incubations also showed a strong biotic influence on DOC and DON dynamics. Despite efficient uptake of added DOM, background DON and high molecular mass DOC concentrations increased downstream, resulting in higher DOM loads than could be accounted for by groundwater discharge and suggesting net release of less bioavailable forms from the channel/hyporheic zone. At the same time, subsurface DOM was characterized by very low C:N ratios and a disproportionately large DON pool despite rapid hydrologic mixing with dilute and high C:N ratio surface waters. Analysis of expected DON loads from conservative hyporheic fluxes indicated that watershed losses of DON would have been seven times greater in the absence of apparent benthic demand, suggesting tight internal cycling of subsurface DON. Our study further demonstrates the potential for significant transformation of N in headwater streams before export to downstream ecosystems.

Key words: cycling; dissolved organic carbon; dissolved organic nitrogen; forest stream; headwater catchment; hydrologic losses; nutrient uptake; spiraling.

INTRODUCTION

Nitrogen (N) availability can control biological activity from cells to ecosystems. For stream ecosystems, the balance between biotic demand and hydrologic transport determines the relative retention of N. Within small watershed ecosystems (sensu Likens and Bormann 1995), streams are the last step in the hydrologic continuum extending from the atmosphere through terrestrial and aquatic subsystems, and thus the final opportunity for biotic regulation of N before transport to downstream ecosystems. Headwater streams are biogeochemically responsive to N, exhibiting rapid uptake of dissolved inorganic N (DIN; Peterson et al. 2001) and may also act as DIN transformers by affecting the relative abundance of N forms comprising total dissolved nitrogen (TDN).

Nitrogen demand in forest streams, as in forest soils (Currie 1999), is strongly linked to microbial cycling

of N contained in organic matter (Triska et al. 1984). In streams, dissolved organic matter (DOM) often constitutes the largest component of the organic matter pool (McKnight et al. 2003) and its flux from rivers often dominates organic loading to estuaries (Seitzinger and Sanders 1997). Dissolved organic N (DON) represents a major pool of dissolved N in many unpolluted headwater catchments (Triska et al. 1984, Lewis 2002, Perakis and Hedin 2002) but it is unclear to what extent N demand in streams is satisfied through accessing the N bound in DOM. Much of the DON in streams is believed to originate from soil as refractory humic and fulvic acids (Qualls and Haines 1991, 1992) and thus may behave conservatively along catchment flow paths (Hedin et al. 1995). Alternatively, forest streams are known to be major generators of dissolved organic carbon (DOC) via microbially mediated leaching of terrestrial detritus (Meyer et al. 1998). Production of DON may be high in forest streams as reflected in large differences in microbial and detrital C:N stoichiometry (Caraco and Cole 2003). Internally produced DON may constitute a relatively fast-turnover com-

partment of N relative to terrestrial sources and thus an important part of the N economy of forest streams.

The importance of DON to biotic N uptake should vary with the degree of N limitation and DOM quality (Kaushal and Lewis 2003, Neff et al. 2003). Amino acids and other monomers are a small proportion of DOM in surface waters (McKnight et al. 2003), but are the most rapidly consumed forms of DOM in stream sediments (Fiebig 1997, Findlay and Sinsabaugh 2003). They thus represent a labile end member capable of playing a disproportionate role in ecosystem metabolism and transformation of N.

In streams, the downstream advection of water imparts a spatial dimension to nutrient cycling. This dimension has been described in terms of spiraling length (S): the distance over which a nutrient transforms from inorganic to organic and back to inorganic form (Webster and Patten 1979, Newbold et al. 1981). Diffusive and capillary forces dictate flow and organize nutrient cycling in unsaturated soils (Wagener et al. 1998) such that residence times are long and transport distances are minimized. In contrast, streams are dominated by advective transport, though zones of relatively slow water movement can have strong influences on system biogeochemistry (Triska et al. 1989, Thomas et al. 2003).

In this study, we examined DON dynamics in surface and subsurface zones of a low DOC, N-limited forest stream via experimental additions of DIN and labile DOM at summer baseflow. Our central objective was to assess how the coupled spiraling of C and N translates into stream ecosystem N fluxes. We hypothesized that in N-limited streams, benthic biota should be capable of significant uptake and transformation of DON, but demand should be mediated by DIN and DOC availability and DOM quality. We tested these hypotheses with experiments addressing how hydrologic exchange, N availability, and DOM quality interact to affect whole-stream N cycling and dissolved N losses.

METHODS

Study site

We conducted this research in Hugh White Creek (HWC), a second-order stream draining a 61-ha catchment in the Coweeta Hydrologic Laboratory in the Appalachian Mountains of southwestern North Carolina, USA. Climate is humid marine with moderate mean annual temperature (13°C) and >90% annual precipitation (187 cm) occurring as rain. Catchment vegetation is dominated by mixed oak, hickory, and tulip poplar forest, with birch and hemlock along streamsides (Webster et al. 1997). A dense understory of rhododendron shades many sections of the stream, resulting in <5% incident light. Low gross primary production (~6 g·m^{-2}·yr^{-1}) and high input of terrestrial detritus (~600 g·m^{-2}·yr^{-1}) result in a highly heterotrophic ecosystem (Webster et al. 1997). Stream water is characterized by low concentrations of DOC (<1 mg/L) and inorganic N (<20 μg/L) and phosphorus (<2 μg/L) (Munn and Meyer 1990, Swank and Vose 1997). Channel sediments are dominated by gravels and cobbles, interspersed with sand and bedrock outcrops. Catchment soils are underlain by deep saprolite, which is thought to be the primary source of baseflow (Velbel 1988). HWC has remained undisturbed since 1924 and is a reference site for long-term hydrologic and chemical monitoring (Swank and Vose 1997).

Experimental design and instrumentation

We combined three complementary approaches to study DON cycling in HWC: (1) whole-stream additions of nitrate (NO$_3$-N) and/or labile DOM, (2) hydrological and biogeochemical modeling, and (3) laboratory experiments with native stream sediments amended with labile DOM. The study reach on the main channel of HWC extended ~700 m upstream of a weir at the base of the watershed. In 1999, we established well transects for sampling subsurface water chemistry located at 69, 95, 110, and 159 m below the head of the reach. Transects were composed of 3 to 4 wells distributed across the wetted channel width. Wells (n = 15) consisted of 5-cm PVC casings (closed bottom) with 15-cm length slotted screens (254-μm slot) inserted ~25 cm beneath the channel bottom.

Additions of NO$_3$-N and DOM

Nutrient enrichment experiments were conducted from 19–21 July 2003 and consisted of sequential individual additions of (1) NaNO$_3$, (2) urea, (3) glutamic acid, and (4) glutamic acid + NaNO$_3$. We used glutamic acid and urea because they differ in C:N mass ratio and molecular mass (L-glutamic acid, Sigma-Aldrich G2128, C:N = 4.3, MW = 147; urea, Sigma-Aldrich U0631, C:N = 0.43, MW = 60; Sigma-Aldrich, St. Louis, Missouri, USA), and thus potentially in bioavailability. The glutamic acid + NaNO$_3$ addition was conducted to assess effects of elevated DIN on DON and DOC uptake.

All solutes were dissolved in deionized water with NaCl as a conservative tracer added to elevate Cl$^-$ concentration 3 mg/L above background (~0.55 mg/L) and increase electrical conductivity ~12 μS. Background NO$_3$-N varied from 3 to 20 μg/L and a NaNO$_3$ solution was used to elevate N concentration by 50 μg/L. DOM was added to elevate stream DON by 300 μg N/L above background (15–80 μg N/L), an enrichment that allowed quantification of N and C above background variability for both DOM forms. Nutrient additions temporarily elevated N:P ratios above that characteristic of baseflow conditions. Additions resulted in a DOC enrichment of 1290 μg C/L for glutamic acid and 129 μg C/L for urea.

Prior to the initial addition, we placed datalogger mini-sondes (HydroLab, Austin, Texas, USA) at 200 (immediately upstream of a small tributary), 300, and

650 m downstream of the addition site. Sondes recorded specific electrical conductance every 4 min. Background stream water samples ($n = 4$) were collected prior to each nutrient release at eight longitudinally distributed stations: -5 m (upstream reference site), 30, 60, 90, 150, 220, 300, and 650 m downstream of the addition site. Hyporheic water was sampled in all wells ($n = 15$) prior to the initial $NaNO_3$ release and at one well from each of four transects prior to subsequent releases using screened vinyl tubing and a syringe. Samples were filtered (Whatman GF/F, pore size $= 0.7$ μm) into acid-washed 125-mL polyethylene bottles and frozen until analyzed for NO_3-N, NH_4-N, DON, and DOC. Specific conductance, temperature, and dissolved oxygen (DO) were recorded at each station and in each well using YSI conductivity and DO meters (YSI, Yellow Springs, Ohio, USA).

Nutrients were pumped from individual carboys using a fluid metering pump (FMI, Syosset, New York, USA) and delivered to a well-mixed location in the stream at 25 mL/min for $\sim$5 h. Additions were conducted on different days, separated by >18 h to ensure adequate hydrologic flushing. During each release, we tracked Cl^- by monitoring specific conductance at the 300-m station until the signal stabilized ($\sim$3.5 h). We then sampled during the ''plateau'' as described for background sampling. After sampling during the glutamic acid release (day 3), the addition was allowed to continue while a second pump simultaneously introduced $NaNO_3$ to the stream. We sampled wells simultaneously with stream sampling during $NaNO_3$ and glutamic acid + $NaNO_3$ ($n = 4$ wells) and urea and glutamic acid additions ($n = 10$ wells).

Hydrology and transient storage modeling

Stream discharge ($Q = $ L/s) was determined using dilution gauging techniques (Webster and Ehrman 1996). Stream depth (z) and width (w) were measured at regular intervals along the 650-m reach. We developed a standard curve relating specific conductance (μS/cm) to Cl^- concentrations (μg/L) in the stream ($Cl^- = 278.8$ μS $- 2408.7$, $r^2 = 0.99$). Lateral inflow (Q_L, L·m^{-1}·s^{-1}) was determined from longitudinal patterns of Cl^- dilution. Hydrologic variables were determined by comparing numerical solutions of a one-dimensional advection–dispersion transport model that includes transient storage and lateral inflow (Bencala and Walters 1983) with observed Cl^- concentrations using a model fit program similar to and in conjunction with OTIS-P (Runkel 1998).

Modeled variables included stream discharge (Q), lateral inflow (Q_L, L/s), the coefficient of exchange between the stream channel and the transient storage zone (α, s^{-1}), and the cross-sectional areas of the open channel and the theoretical transient storage zones (A and A_s, m^2). Using model results, we calculated mean water velocity ($u = Q/A$), uptake length for water ($L_s = u/\alpha$), mean storage zone water residence time ($T_s = $

$A_s/\alpha A$), and the transient storage exchange flux ($q_s = \alpha A$) as described by Harvey and Wagner (2000). The upper 300-m reach of stream was used for hydrologic modeling because it included all well locations and most surface water transects. Percentage surface water in hyporheic wells was determined with a mixing model that compares change in Cl^- concentrations in surface vs. well waters (Triska et al. 1989).

In February 2004 (during a period of similar flow as July 2003), we independently assessed the residence time of hyporheic water by injecting $\sim$2 mL of NaCl solution (1 g Cl^-/L) into a subset of individual wells ($n = 8$, two per transect) and tracking Cl^- clearance curves via exponential decay in specific conductance (k_c, h^{-1}) over time ($\sim$2 h). Mean water residence time (h) was calculated as $1/k_c$.

Nutrient uptake, production, and transformation

We estimated nutrient uptake lengths (S_w; the average distance traveled by a reactive solute) as $1/k_L$, where k_L is the longitudinal loss rate (m^{-1}) determined with linear regressions of the natural ln-transformed background-corrected plateau N:Cl or C:Cl ratios against distance downstream (Newbold et al. 1981). Uptake velocity ($v_f = Q/wS_w$, mm/min) and rate ($U = v_f C$, mg·m^{-2}·d^{-1}) were calculated to determine mass transfer and areal influxes of nutrients, where w is mean stream width and C is background concentration (Stream Solute Workshop 1990).

Mineralization of DON was estimated by fitting a two-compartment mass balance model to the longitudinal profile of added DON and NO_3-N loads to produce best-fit estimates of simultaneous DON consumption (k_{DON}) and NO_3-N production (k_{NIT}) and uptake (k_{NO_3}) following Mulholland et al. (2000). The preliminary step of ammonification of DON to NH_4-N was ignored because we were unable to detect a NH_4-N response in surface waters to DON additions. Nitrification fluxes were calculated as $k_{NIT}/k_{DON} \times U_{DON}$ using the geometric mean of added longitudinal DON concentrations. We were unable to calculate nitrate uptake or nitrification for the glutamic acid + nitrate experiment because of source ambiguity of elevated NO_3-N. We assessed net consumption or production in the hyporheic zone by comparing observed background-corrected plateau N and C concentrations in wells vs. expected values derived from Cl^- concentrations assuming conservative transport from the nearest upstream surface transect (sensu Triska et al. 1989, Valett et al. 1996).

We calculated ''realized'' production rates for chemicals that increased in concentration downstream (i.e., increases in load were greater than increases in discharge) by multiplying the up-to-downstream concentration difference by downstream Q and dividing the resultant load by total benthic surface area (Meyer et al. 1998). We also calculated ''expected'' loads based on conservative subsurface-to-surface nutrient fluxes using $q_sC_H + Q_LC_S$ adjusted for stream width, where

C_H is the mean background hyporheic nutrient concentration for all well samples and C_S is the mean background stream nutrient concentration at the transect above the addition point. Expected stream loads were calculated by adding resultant hyporheic fluxes to stream loads derived from upstream surface water concentrations and Q_L (i.e., nutrient loads conservatively tracking water inputs).

Laboratory microcosms

We assessed the relative importance of biotic and abiotic uptake of DOM by conducting short-term batch incubation experiments. After field experiments, ~2 kg of native sediments were collected from a tributary entering HWC at 200 m and were kept in the laboratory at 4°C until initiating microcosm assays (3 d). Sediment was first reacclimated to ambient stream temperatures (15°C) for 24 h, sieved (1-cm mesh), and homogenized. To eliminate biotic activity, half of the sediments were saturated with a solution of $HgCl_2$ (100 mg/L; Dahm 1981). We then added 50 cm³ (~83 g, ~1% OM) of well-drained live or dead sediments into 500-mL flasks across three treatments: (1) deionized (DI) water (200 mL), (2) DI water + urea, and (3) DI water + L-glutamic acid, with four replicates each ($n = 24$). We added 60 μL of concentrated DOM to enrich water by 300 μg DON/L. Water and water + $HgCl_2$ controls were used to correct for background release of C and N from sediments. Flasks were shaken at 125 rpm and 15°C for a total of 4 h. At 0.5 and 4 h, ~30 mL of supernatant was drawn off for analysis. Samples were filtered (GF/F), stored in polyethylene bottles, and frozen. Uptake was analyzed as change in nutrient mass per gram of sediment.

Analytical chemistry

Nitrate-N was determined colorimetrically following the acidic diazo method after cadmium reduction (Wood et al. 1967) on a Technicon auto analyzer II (Technicon, Emeryville, California, USA). Ammonium-N was analyzed colorimetrically following an automated phenate method (Soloranzo 1969). Total dissolved N (TDN) was determined by high temperature potassium persulfate oxidation followed by analysis of nitrate. DON was calculated by difference as TDN − (NO_3-N + NH_4-N) using L-glutamic acid as a reference standard (D'Elia et al. 1977, APHA 1998). DOC was determined by sodium persulfate oxidation using a total organic carbon analyzer (Model 700, Oceanographic International, College Station, Texas, USA; Menzel and Vacarro 1964). A subset of background and plateau samples were analyzed for Cl^- using a Dionex 500 ion chromatograph (Dionex, Atlanta, Georgia, USA) equipped with an AS14 anion detection column (APHA 1998). To assess large molecular mass humic substances, background samples were analyzed for specific ultraviolet absorbance (SUVA) at 254 nm using a 10-cm path cell in a Shimadzu spectrophotometer (Shimadzu, Tokyo, Japan; Chin et al. 1994).

Statistical analysis

Spatial patterns in background nutrients were analyzed with linear regressions of concentrations and fluxes with distance downstream. We tested for differences among uptake slopes (k) of added nutrients by assessing the interaction term between distance downstream and added nutrient type with multiple linear regression (Zar 1984). We tested for differences between stream and hyporheic concentrations, expected and observed plateau hyporheic concentrations, and differences between live vs. dead sediment treatments using paired t tests. We compared observed vs. expected increases in nutrient loads using chi-square analysis. All statistical tests were performed using SAS (SAS Institute 1997).

RESULTS

Hydrologic dynamics

Discharge increased from 8.7 to 20.2 L/s over the first 300 m of study reach, representing a lateral inflow rate of 0.016 $L·s^{-1}·m^{-1}$. At the same time, results from transient storage modeling (Appendix A) showed that the transient storage exchange flux (q_s) was 0.052 $L·s^{-1}·m^{-1}$, suggesting that >3 times the volume of water was exchanged with transient storage than was discharged from groundwater per length of stream channel. This relationship was mirrored by mixing within the hyporheic zone, where percentage surface water averaged 72.2 ± 9.5% (mean ± SE) in sampling wells. The uptake length of water (L_s) was 417 m, and 71% of all surface water was exchanged with the storage zone over the 300 m reach. Water residence time in transient storage (T_s) was 1.1 h, a value very similar to that derived for hyporheic wells (1.9 ± 0.4 h; $n = 8$). The relative size of the transient storage zone (A_s/A) was 0.8.

Background chemistry

Stream water was well oxygenated and characterized by low concentrations of NO_3-N (11 ± 0.1 μg/L) and NH_4-N (2 ± 0.3 μg/L; Fig. 1). Stream water DON concentrations were significantly ($P < 0.01$) higher than DIN and represented ~65% of stream TDN (Fig. 1). Low DOC and high atomic C:N ratios (range = 25–96; mean ± SE = 50 ± 4) characterized stream DOM. In contrast to stream water, hyporheic well water was significantly ($P < 0.01$) elevated in DIN (NO_3-N = 33 ± 7 μg/L; NH_4-N = 8 ± 1 μg/L), DON, and DOC, and depleted in DO (Fig. 1). DON also dominated (~89%) TDN in the hyporheic zone. High DON and only moderately elevated DOC resulted in very low hyporheic DOM C:N ratios (1.5–14.3; 6 ± 1) compared to stream DOM. SUVA analysis of well samples ($n = 4$) indicated overlap between subsurface and sur-
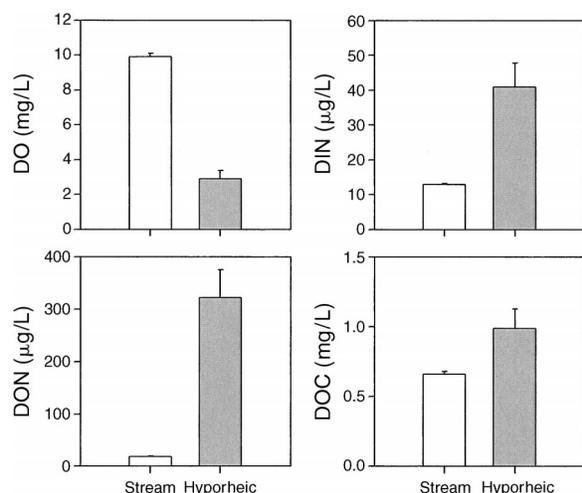

FIG. 1. Comparison of background stream and hyporheic water chemistry (mean ± SE): DO, dissolved oxygen; DON, dissolved organic nitrogen; DIN, dissolved inorganic nitrogen; DOC, dissolved organic carbon. Means were significantly ($P < 0.01$) different as determined by paired t tests.

face values (1.9 ± 0.2 vs. 2.0 ± 0.1 L·mg C^{-1}·m^{-1}). Although NO$_3$-N concentrations were highest at the transect most downstream (19.2 ± 0.1 μg/L), the regression with distance downstream was not significant ($P = 0.56$) without this point. In contrast, stream concentrations of DON and DOC and SUVA values increased significantly ($P < 0.01$) with distance downstream at both scales (Fig. 2). These results indicate greater increases in dissolved organic C and N loads than could be accounted for by increases in discharge, indicating an important channel/hyporheic source of nutrients other than groundwater.

Nutrient uptake and transformation

HWC exhibited strong and differential uptake of added DOM and DIN. DON was taken up at a significantly ($P < 0.05$) higher rate than either NO$_3$-N alone or DOC within the DOM pool (Table 1). After correction for dilution, only ~6% of added DON remained 300 m downstream of the addition site during the experimental additions. Longitudinal loss rates (k_L) for DOC and DON were similar ($P > 0.05$) between urea

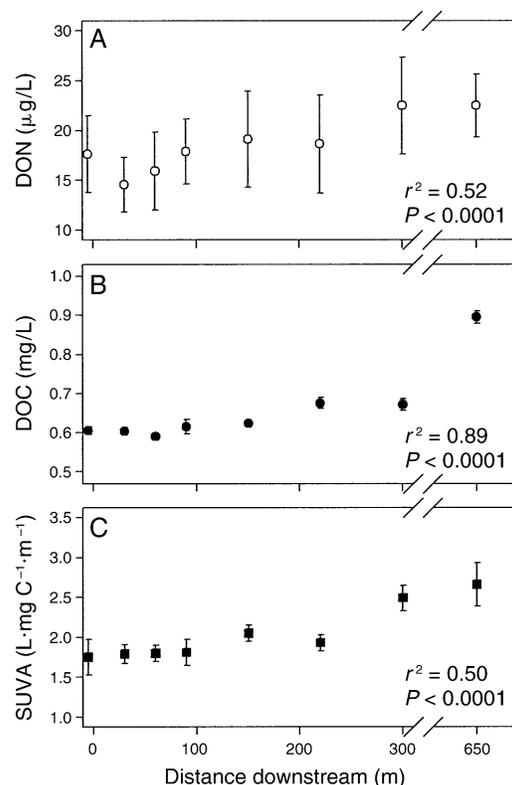

FIG. 2. Background longitudinal patterns in ambient stream (A) DON, (B) DOC, and (C) SUVA (specific ultraviolet absorbance) values in Hugh White Creek, North Carolina, USA. Data are means ± SE ($n = 4$ per location). Statistics are from regressions of all samples against distance downstream. Regressions remained significant ($P < 0.01$) following removal of data for 650 m.

and glutamic acid additions. Differential uptake of C and N during urea and glutamic acid additions resulted in mass ratios of C and N uptake ($k_{DOC}:k_{DON}$) of 0.8 and 0.65 and areal C and N uptake ($U_{DOC}:U_{DON}$) of 0.9 and 3.6, respectively. Addition of NO$_3$-N during the glutamic acid experiment substantially increased uptake of DOC and DON (Table 1) but more so for C, thus shifting the stoichiometry of DOM uptake ($k_{DOC}:k_{DON}$ = 1.2 and $U_{DOC}:U_{DON}$ = 6.5).

Rapid nitrification of added DON resulted in significant ($P < 0.01$) increases in surface water NO$_3$-N con-

U (mg·m^{-2}·d^{-1})‡	9.3	295.0	311.0	1155.0	324.0	2726.8	416.2

† Different superscripted letters indicate significant ($P < 0.05$) differences among uptake coefficients (k_L).

‡ Areal uptake is based on background concentrations for NO$_3$-N and the geometric mean of added concentrations for dissolved organic carbon (DOC) and dissolved organic nitrogen (DON).
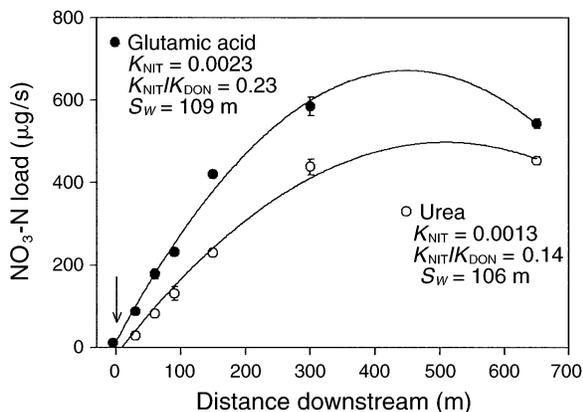

FIG. 3. Nitrate production curves during urea (open circles) and glutamic acid (solid circles) additions. Values are mean ($\pm$ SE) background-corrected nitrate loads. Included are results from the mass balance model for the longitudinal nitrification rate (k_{NIT}), the proportion of DON uptake nitrified (k_{NIT}/k_{DON}), and simultaneous nitrate uptake lengths (S_w). The arrow indicates the nutrient addition site.

centrations (Fig. 3). Although most DON was taken up within the first 300 m, elevated NO_3-N concentrations were evident at the base of the watershed (650 m). Extremely rapid and transitory ammonification was suggested by stable and low NH_4-N concentrations in surface and subsurface waters during DOM releases. Nitrification rates accounted for 14% and 23% of urea-DON and glutamic acid-DON uptake, respectively (Fig. 3).

The mass balance model produced estimates of nitrate uptake lengths three times shorter than those calculated from the NO_3-N addition (Fig. 3, Table 1). Adding DON and produced NO_3-N uptake lengths resulted in a total N spiraling length (S) of 209 and 210 m. Combining all S_w estimates for NO_3-N indicated that background net uptake could have varied from 9 to 31 mg N·m^{-2}·d^{-1}. By comparison, net nitrification calculated using background and added DON levels varied from 7.4 to 46.9 mg N·m^{-2}·d^{-1}.

Although we found rapid uptake of added DON in surface waters, analysis of hyporheic concentrations suggested that DON was transported conservatively to the hyporheic zone where observed and expected concentrations were not significantly different ($P = 0.92$, paired t tests; Fig. 4A). Concentrations of NH_4-N did not differ between background and plateau samples ($P > 0.2$). During the same period, 22 out of 24 samples showed net production of NO_3-N ($P < 0.001$; Fig. 4B). In contrast, we found that the hyporheic zone was a net consumer of added DOC ($P = 0.047$) in 18 of the 24 samples (Fig. 4C).

Sediment microcosms

Dissolved organic matter was released over time from killed (DOM C:N = 16) and live (DOM C:N = 25) control sediments. Background release of DON was

greater ($P < 0.05$) in killed (3.1 $\pm$ 0.5 μg N/g sediment) vs. live (1.4 $\pm$ 0.3 μg N/g sediment) controls (Appendix B). Release of DOC was also greater ($P < 0.05$) in killed vs. live sediments but concentrations decreased in live sediments and accumulated in killed

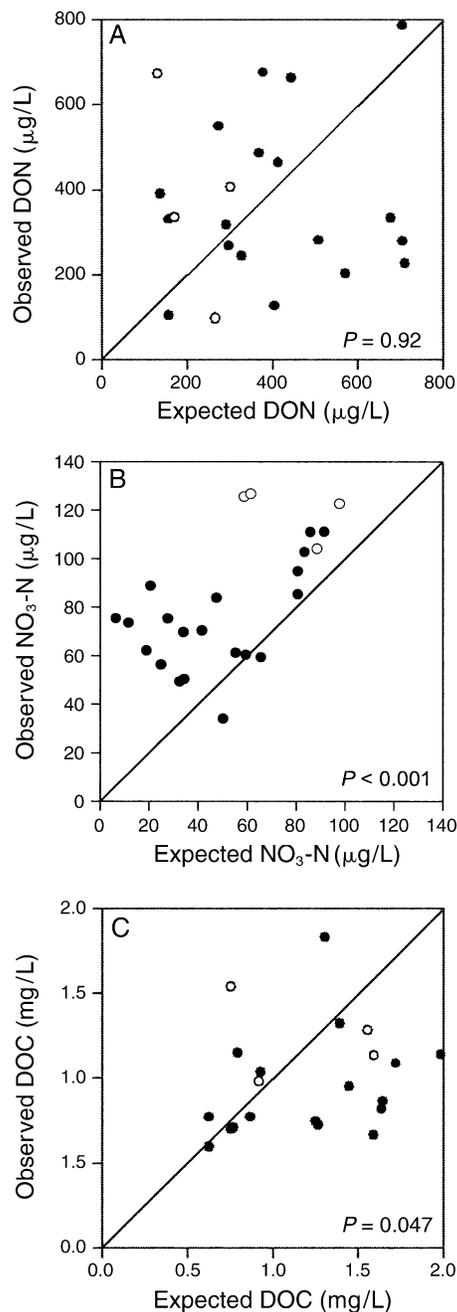

FIG. 4. Subsurface responses to both urea and glutamic acid additions (solid circles) and glutamic + NO_3-N (open circles) showing (A) DON, (B) production of NO_3-N, and (C) consumption of DOC. Values above the 1:1 observed–expected line indicate net production, while values below the line indicate net consumption. P values are for results of paired t tests.
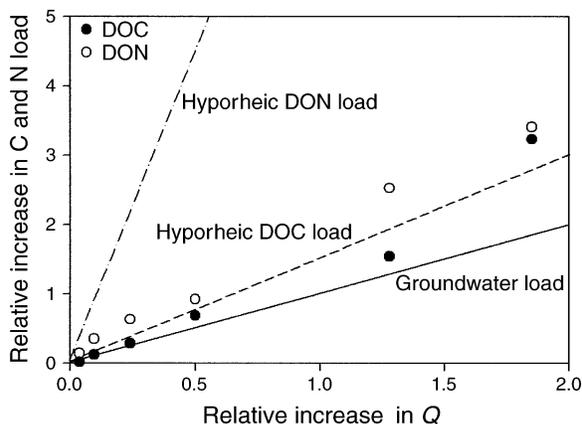

FIG. 5. Increase in DOC and DON load vs. increase in water load (Q, stream discharge). Values represent the proportional increase in nutrient load at downstream transects relative to loads at the transect most upstream. The solid line represents the proportional increases in discharge and expected nutrients if nutrient loads tracked groundwater inputs (1:1 line). Dashed lines represent expected DOC and DON loads based on conservative transport of hyporheic concentrations.

sediments over time. All live treatments tended toward net consumption of added DOC and DON compared with net production in killed treatments, but differences were significant only for glutamic acid and control DOC treatments (Appendix C). Nitrification in live sediments was indicated by increases ($P < 0.01$) in NO_3-N but constant NH_4-N levels. In contrast, NH_4-N accumulated in killed treatments (Appendix B).

Stream fluxes and watershed losses

Downstream increases in concentration (Fig. 2) translated to net production of DOC (79.4 mg·m^{-2}·d^{-1}) and DON (2.1 mg·m^{-2}·d^{-1}). However, observed increases in DON load were significantly lower ($\chi^2 = 24.3$, $P < 0.001$) than expected based on conservative hyporheic fluxes (Fig. 5). Export of DON from the study reach would have been seven times greater than the observed 50 g/d had hyporheic DON been transported conservatively to surface waters and downstream (i.e., 350 g/d). This translates to uptake of hyporheic DON of 478.2 mg·m^{-2}·d^{-1} along the hyporheic-stream flow path, similar to the mean observed uptake of experimentally added DON ($U_{DON} = 317.5$ mg·m^{-2}·d^{-1}). In contrast to apparent removal of DON, this analysis indicated subsurface DOC fluxes would result in loads equivalent ($\chi^2 = 0.4$, $P > 0.25$) to realized loads.

DISCUSSION

Passive hydrologic transport vs. tight internal cycling of organic nutrients

Our study provides evidence for whole-stream uptake and transformation of labile DON and indicates multiple potential interactions of DOC and DON in forest streams. Despite rapid uptake of added DOM, we found that the stream was a net producer of DOC and DON, resulting in watershed losses greater than expected from groundwater alone. Differential patterns of C and N uptake and production indicate that hydrologic exchange and biotic demand in forest streams can significantly influence watershed N losses.

Coweeta streams are strongly N-limited in part due to extremely low hydrologic N losses from surrounding forest ecosystems (Swank and Vose 1997). Our study showed pronounced uptake of monomeric DON and DOC in HWC, suggesting strong biotic demand for DOM in the face of low ambient N and C availability. Uptake lengths of DOC and DON were similar to that reported for a sucrose addition to HWC (Munn and Meyer 1990) but were longer than those observed for ^{13}C-acetate additions (~ 10 m) in other Coweeta streams (Hall and Meyer 1998). Further, addition of NO_3-N during the glutamic acid experiment showed that uptake of labile DOM, especially DOC, is highly responsive to DIN availability. Together, these observations suggest that DON uptake was mediated by demand for DOC and in turn C demand was mediated by DIN. The shift in the C:N stoichiometry of uptake resulting from addition of DIN illustrates enhanced C uptake at times of high N availability. Accordingly, it also suggests higher labile DON demand in the face of lower DIN availability. These results support the idea of a strong link between inorganic N dynamics and DOC availability (Bernhardt and Likens 2002) and tight coupling of DOC, DIN, and DON spiraling in forest streams. Combined uptake lengths for DON and NO_3-N indicate that multiple complete N transformations may occur along the stream reach. Our results support the notion that low abundance of labile DOM in surface waters may in part be a function of internal biotic demand by microbial biofilms (Kaplan and Newbold 2003, Battin et al. 2003) and are consistent with the idea that much of aquatic metabolism is supported by rapid turnover of low molecular mass DOM (Kirchman 2003).

In small streams, efficient biotic uptake of dissolved nutrients is associated with longer water residence times. Modeling and field measurements demonstrated strong surface–subsurface water exchange in HWC. Hydrologic exchange with longer residence time compartments is a key driver of DIN dynamics in many stream ecosystems (Triska et al. 1989, Valett et al. 1996, Thomas et al. 2003). We found the relationship between the transient storage exchange flux (q_s) and lateral inflow (Q_L) to be particularly useful for studying DON dynamics. Similar potential for DON transformation likely exists in other streams given that hydrologic metrics calculated for HWC are in the middle of published values for a variety of streams (Runkel 2002).

Large subsurface N pools exist despite rapid hydrologic mixing with dilute surface waters, suggesting in-

ternal production. Indeed, DON concentrations are generally higher in subsurface vs. surface waters across a broad range of headwater forest streams in the southern Appalachian Mountains (E. N. J. Brookshire, *unpublished data*). Concentrations of DOC and DON decline with depth in mineral soils via rapid adsorption (Qualls and Haines 1991), resulting in near-stream groundwater DOM similar to stream water (Meyer and Tate 1983, Qualls and Haines 1991, Golladay et al. 1992), implying that groundwater inflow could not have produced elevated hyporheic DON concentrations. Further, conservative three-compartment (surface, hyporheic, and groundwater) mixing analysis (sensu Mulholland and Hill 1997) indicated that, given the high level of surface–subsurface mixing compared to lateral inputs, groundwater DON would have had to be unrealistically high ($\geq$1310 μg/L) to produce observed hyporheic concentrations (E. N. J. Brookshire, *unpublished data*). At the same time, longitudinal increases in stream DON concentrations indicate net DON release. Several possible mechanisms may explain these patterns. Most DOC and DON in soils and stream waters of Coweeta are found in refractory humic and fulvic acids (Qualls and Haines 1991, 1992), consistent with the high C:N ratio and elevated SUVA values (McKnight et al. 2003) of surface water DOM found in our study. Previous studies in HWC also found longitudinal increases in DOC and high molecular mass DOM (Meyer and Tate 1983). Further, work in Coweeta has identified channel-stored terrestrial particulate organic matter (POM) as the primary source of the observed DOC (Meyer et al. 1998). This is consistent with our findings that expected DOC loads from hyporheic fluxes were indistinguishable from realized loads. Similar longitudinal increases in DON observed in our study and large benthic pools of particulate organic N (12.6 g/m^2; Webster et al. 1997, Tank et al. 2000) suggest DON production may also be linked to in-stream detrital-N, presumably via hydrolysis and leaching.

Although longitudinal increases in DON suggest net release of less bioavailable forms, convergence of our experimentally determined labile DON uptake with that required to balance conservative hyporheic fluxes argues for very high consumption of internally produced DON, otherwise watershed losses would have been much higher. The low C:N ratios of hyporheic DOM observed in HWC were similar to microbial biomass (Tank et al. 2000), suggesting a microbial origin of hyporheic DON. Production and uptake of amino acids by heterotrophic bacteria is common and constitutes a major internal flow of energy and nutrients in lake and marine ecosystems (Kirchman 2003). Similarly, Fiebig (1997) demonstrated tight microbial recycling of amino acid-C in hyporheic sediments and Findlay and Sinsabaugh (2003) found comparable uptake of DIN and amino acid-N by hyporheic biofilms and widespread capacity for DON uptake across bacterial taxa. Our sediment experiments also showed a strong biotic influence on amino acid-N uptake and revealed a large pool of DON in stream sediments.

Given close coupling of particulate and dissolved organic forms (sensu Meyer et al. 1998), increasing N content of POM associated with decomposition and N immobilization could also influence low C:N ratios of DOM. Tank et al. (2000) found minimal labeling of surface water DON during a ^{15}N-NH$_4$ addition to a nearby Coweeta stream, implying slow turnover of most surface water DON relative to transport. However, mass balance of ^{15}N-NH$_4$ additions and others conducted with ^{15}N-NO$_3$ in Coweeta (H. M. Valett, *unpublished data*) generally yield $\sim$50% or less isotopic recovery, suggesting that some of the missing N may have gone to subsurface pools. Differential gaseous losses of C and N could also reduce C:N ratios. Metabolic losses of CO$_2$ are large in HWC (Webster et al. 1997) while N losses via denitrification are presumably much smaller. Increases in subsurface NO$_3$-N and decreases in DOC during DOM experiments and only moderately elevated background DOC relative to surface water concentrations were also consistent with decreasing N limitation and increasing C limitation with depth, similar to hyporheic zones of other N-limited forest streams (Triska et al. 1989).

The large DIN pool in the hyporheic zone of HWC and rapid nitrification of added DON points to mineralization and subsequent benthic uptake as a potential fate of consumed DON. While we are aware that subsurface redox conditions and related N transformations can be very spatially heterogeneous (Baker et al. 2000), subsurface N accumulation and strong depletion of DO suggest that nitrification was mostly restricted to the benthic interface, and deeper subsurface concentrations of NO$_3$-N were due to conservative transport of nitrate-rich infiltrating water. Microbial demand and regeneration appear to be equivalent, resulting in lack of longitudinal gradients in NH$_4$-N and NO$_3$-N concentrations in this stream. Further, the lack of an ammonification signal to DON additions is consistent with very rapid uptake of NH$_4$-N in Coweeta streams (Hall et al. 1998, Tank et al. 2000). Conditions generated by our experiments may have restricted NH$_4$-N cycling to the scale of the biofilm itself. Denitrification and downstream loss or deep burial as FPON, perhaps of biofilm origin, are also potential but poorly understood fates of dissolved N.

Our study was conducted during summer baseflow when nutrient uptake is likely higher than during periods of high flow and colder temperatures. DOC concentrations and fluxes increase during storms relative to baseflow (Meyer and Tate 1983) and the same may apply to DON. Also, DIN uptake in Coweeta is highest after leaf-fall (H. M. Valett, *unpublished data*) reflecting increases in microbial demand associated with decomposition. Given the observed relationship between DON and DIN uptake, labile DON uptake may also increase during fall. However, stream NO$_3$-N concen-

trations and fluxes (Swank and Vose 1997) and subsurface DON concentrations (E. N. J. Brookshire, *unpublished data*) in Coweeta are highest during summer, suggesting a potentially important role of summer N cycling to annual watershed N losses.

Our results support the idea of an important role for DON production in forest streams (Caraco and Cole 2003). We propose two major pools of DON in HWC: (1) refractory DON derived primarily from catchment soils and secondarily from in-stream detrital leaching; and (2) labile internally recycled DON. This framework is consistent with fast and slow turnover pools described for stream DOM (Kaplan and Newbold 2003) and terrestrial DON (Neff et al. 2003). Our results suggest extremely short spiraling lengths for monomeric DON and much longer (i.e., at the scale of river networks) spiraling of complex, predominantly humic, terrestrial DON.

Large increases in global N availability via human activities (Vitousek et al. 1997) require better understanding of biotic controls on cycling of N at ecosystem scales. The results presented here argue for a much more influential role of stream biota in modulation of watershed DON losses than is commonly assumed. Our estimates of DIN and DON spiraling suggest that a significant portion of the dissolved N pool is transformed as it moves through headwater streams. Further, this study provides support for the idea that even small increases in DIN availability may alter ecosystem DOC and DON dynamics.
